Current techniques used for the correction of permanent and complete facial paralysis involve static or dynamic procedures. With the introduction of the innervated, vascularized free muscle transfer, a large jump was made in both aesthetics and function.\(^1\) The procedure, designed to address lower facial nerve palsy, is highly successful in achieving excursion of the oral commissure and bilabial closure. The result has been an improvement in dynamic smile reanimation. The muscle (e.g., gracilis, latissimus dorsi, biceps femoris, serratus anterior, pectoralis minor) may be staged with cross-face nerve grafting using the contralateral functioning

**Background:** Free muscle transfer for dynamic smile reanimation in facial paralysis is not always predictable with regard to cosmesis. Hospital stays range from 5 to 7 days. Prolonged operative times, longer hospital stays, and excessive cheek bulk are associated with free flap options. Lengthening temporalis myoplasty offers single-stage smile reanimation with theoretical advantages over free tissue transfer.

**Methods:** From 2012 to 2014, 18 lengthening temporalis myoplasties were performed in 14 children for smile reconstruction. A retrospective chart review was completed for demographics, operative times, length of hospital stay, and perioperative complications.

**Results:** Fourteen consecutive patients with complete facial paralysis were included. Four patients underwent single-stage bilateral reconstruction, and 10 underwent unilateral procedures. Diagnoses included Möbius syndrome (\(n = 5\)), posterior cranial fossa tumors (\(n = 4\)), posttraumatic (\(n = 2\)), hemifacial microsomia (\(n = 1\)), and idiopathic (\(n = 2\)). Average patient age was 10.1 years. Average operative time was 410 minutes (499 minutes for bilateral lengthening temporalis myoplasty and 373 for unilateral lengthening temporalis myoplasty). Average length of stay was 3.3 days (4.75 days for bilateral lengthening temporalis myoplasty and 2.8 for unilateral lengthening temporalis myoplasty). Nine patients required minor revisions.

**Conclusions:** Lengthening temporalis myoplasty is a safe alternative to free tissue transfer for dynamic smile reconstruction in children with facial paralysis. Limited donor-site morbidity, shorter operative times, and shorter hospital stays are some benefits over free flap options. However, revisions are required frequently secondary to tendon avulsions and adhesions. (*Plast. Reconstr. Surg.* 137: 1251, 2016.)

**Clinical Question/Level of Evidence:** Therapeutic, IV.

www.PRSJournal.com
facial nerve or connected directly to an ipsilat-
eral donor nerve, such as the masseter nerve.2–5
The advantage of two stages is spontaneous initiation
of smiling by means of the unaffected contralat-
eral facial nerve branches. Each option carries its
own set of advantages and disadvantages, exten-
sively outlined in previous studies.

However, several persistent flaws exist when
using functional free muscle transfer. First, the
resulting increase in cheek bulk may be difficult
to control, despite accommodation by means of
lipectomy of the soft tissues. This problem may
exist in either the resting state or with animation.
Second, the placement of the nasolabial fold has
proven challenging and can vary widely because of
unpredictable changes that occur with animation.
Its true placement cannot be known with certainty
until reinnervation has occurred and excursion
can be visualized. Third, the optimal vector of oral
commissure excursion is also difficult to predict
intraoperatively, making fine adjustments difficult
to predict. Fourth, surgical times can be exten-
sive and hospitalization may be as long as 5 to
7 days, often requiring admission to the intensive
care unit for flap monitoring. Finally, the time to
achieve excursion of the oral commissure can take
between 2 and 6 months or longer for innervation
to reach the transplanted muscle.

In recent years, Labbé and Huault have repop-
ularized the temporalis myoplasty for lip reanima-
tion.6 Several key refinements were made on the
initial work by McLaughlin in 1949 to improve
results.7 The “lengthening temporalis myoplasty,”
as described, involved mobilizing the ipsilateral
temporalis muscle while keeping the neurovascu-
lar pedicle intact. The insertion of the muscle on
the coronoid is mobilized and transmitted in an
antegrade fashion, deep to the zygoma toward the
upper lip where it is attached to the oral commis-
sure and upper lip.

Aside from a case series reported by Veyssière
et al., there are no other case series on this tech-
nique in the pediatric population.8 Recognizing
the limitations of free muscle transfer for facial
reanimation and the relative paucity of data of
this technique in children, we describe our experi-
ence using the lengthening temporalis myoplasty
in a largely pediatric population.

PATIENTS AND METHODS

Between 2012 and 2014, a total of 18 length-
ening temporalis myoplasty procedures were
performed in 14 consecutive patients. A retro-
spective chart review was performed to determine
diagnosis, laterality, and ancillary procedures
performed. Patient and operative variables col-
lected included age, sex, operative times, length
of hospital stay, perioperative complications,
ancillary procedures, and revisions performed.
Preoperative and postoperative frontal view pho-
tographs were used to assess excursion and vector
symmetry. Excursion was measured on examina-
tion preoperatively and postoperatively at the oral
commissure and the mid upper lip using the ruler
technique described by Manktelow et al.9

Surgical Technique

The surgical technique has been described
previously (Fig. 1).6,10 Preoperative assessments of
excursion of the oral commissure and vector of
pull are made with the patient awake and in the
upright position (Fig. 2). Markings are placed on
the unaffected side, and contralateral markings
are made for symmetry in the setting of unilat-
eral facial nerve palsy. The temporalis muscle is
accessed by means of a coronal incision. The zygo-
matic arch may be osteotomized to expose the
contents of the infratemporal fossa. The tempora-
lis tendon is identified in this space as it inserts on
the coronoid process of the mandible. An oblique
osteotomy releases the coronoid process with the
attached temporalis tendon insertion. This can be
accomplished from the coronal incision above or
through the nasolabial fold incision from below.
After mobilizing the temporalis muscle, the coro-
noid and temporalis tendon are passed as a unit
through the buccal fat pad and into the cheek.
A counterincision is placed carefully along the
future nasolabial fold externally, if not already
done for access to the coronoid process. Symmetry
is determined preoperatively with the patient
actively animating the lip. In the setting of bilat-
eral facial paralysis (e.g., Möbius syndrome), an
arbitrary nasolabial fold incision is placed at the
expected location between the skin of the upper
lip and cheek. The coronoid process is grasped
through this incision and gently pulled through
the buccal tunnel (Fig. 3). The tendon is carefully
stripped, and the bone is discarded. The tempo-
ralis tendon is then opened into a broad, flat con-
figuration from its conical shape. A large area of
insertion is achieved from the oral commissure
into the upper lip, just distal to the nasolabial fold.
The temporalis muscle is rotated at the expense of
the posterior half to allow the tendon to pass
with enough length to avoid an interpositional
graft. The muscle is reanchored in its new config-
uration within the temporalis fossa and tested for
adequate excursion. A muscle stimulator is used.
to create a tetanic contraction to refine the vector of excursion at the oral commissure and reproduce movement as seen on the unaffected side. The tendon insertion is adjusted to replicate the patient’s “normal” smile according to the Rubin classification. An indwelling anesthetic infusion catheter is placed along the neurovascular pedicle to avoid excessive spasm of the temporalis muscle and to provide pain relief.

Ancillary procedures include contralateral zygomaticus major/minor and risorius chemodenervation with botulinum toxin type A (Botox; Allergan, Inc., Irvine, Calif.).11,12 A total of 6 to 8 units of Botox (2 units per 0.1 ml of solution) is injected near the junction between these muscles and the orbicularis oris. Injection into the contralateral, active facial musculature causes relaxation of unopposed contraction and allows the temporalis muscle insertion and origin to anchor in their new position without excessive countertension. This small amount of Botox limited to the distal portions of the muscles only serves to weaken their pull on the upper lip and oral commissure without inducing lip lag on
the unaffected side. In addition, some patients sub-
jectively demonstrating excessive contralateral lower
lip depressor muscle activity underwent transbuccal
myectomy to reestablish lower lip symmetry.13,14

Physical therapy is started 3 weeks after sur-
gery. Goals are to achieve greater mobility and
symmetry, develop spontaneity, and improve swal-
lowing and speech. A physical therapist initiates
a biofeedback program, scar and facial massage,
tendon gliding, motor learning, and a home mirror
(mime) exercise program.

Anatomy

The temporalis muscle originates broadly in
the temporal fossa and the temporal crest. Deep
and superficial layers have been described.15 The
muscle converges from its fan-like orientation to
a unique three-dimensional tendon that inserts
on the coronoid process of the mandible.16 As it
passes deep to the zygomatic arch, there is inti-
mate association with the masseter muscle. Fibers
from the masseter can intermingle and attach to
the temporalis muscle and tendon, thereby poten-
tially limiting excursion underneath the arch.
These masseter fibers can insert as far as 2 cm
above the zygomatic arch onto the deep tempo-
ralis fascia.17

The temporalis is dually innervated by the
anterior and posterior deep temporal nerves, aris-
ing from the anterior division of the mandibular
nerve (V3). Being a muscle of mastication, it is
responsible for powerfully establishing occlusion.
It is a single-vector muscle in this regard and an
ideal candidate for smile reconstruction.

Its arterial supply is from the anterior and
posterior deep temporal arteries, divisions of
the internal maxillary artery. The vessels emerge
within the infratemporal fossa and travel with
the anterior and posterior deep temporal nerves
as they separate from the mandibular nerve
(through the foramen ovale).

Simply disinserting the temporalis tendon
from the coronoid process and stretching it toward
the perioral region is usually insufficient and over-
stretches the native resting length of the muscle.
Tendon or fascial interposition grafts have been
used to make up the difference in length.18 How-
ever, this often results in inadequate excursion.
Lengthening of the temporalis tendon in length-
ening temporalis myoplasty occurs at the expense
of the posterior half of the temporalis muscle.19

RESULTS

A total of 18 lengthening temporalis myoplasty
procedures were performed in 14 consecutive
patients with complete facial paralysis over a 2-year
period (Table 1). Ten patients underwent unilateral
procedures, and four patients had bilateral lengthen-
ing temporalis myoplasty performed. Average
patient age was 10.1 years (range, 5.4 to 17.8 years).
Follow-up ranged from 10 to 34 months, with an
average of 28 months. All patients demonstrated
mobility of the lip along the upper lip and oral
commissure, with nasolabial fold creation. Average
time to animation was 2.5 weeks. Range of oral
commissure excursion was between 5 and 13 mm,
with an average of 8.2 mm. Smiling was activated
coincidently with biting in all patients. No interpo-
sational fascia or tendon grafts were used.

Average operative time was 410 minutes
(499 minutes for bilateral lengthening temporalis
myoplasty and 373 minutes for unilateral lengthen-
ing temporalis myoplasty). Average length of stay
was 3.3 days (4.75 days for bilateral lengthening

temporalis myoplasty and 2.8 days for unilateral lengthening temporalis myoplasty). Five patients had simultaneous contralateral depressor angularis oris myectomy performed for lower lip symmetry. One patient underwent simultaneous lagophthalmos correction, and six patients had injection of Botox into the contralateral zygomaticus major and minor, risorius, and depressor angularis oris muscles. Three patients demonstrated moderate temporal hollowing. These patients did not undergo any further correction, although fat injection was offered. Nine patients required revision of the temporalis tendon insertion site or lysis of adhesions (64 percent), and two patients required blood transfusion during the perioperative period. One patient developed a postoperative infection requiring incision and drainage.

### CASE REPORTS

**Case 1**

A 10-year-old girl (patient 7 in Table 1) developed complete right facial paralysis following resection of a medulloblastoma (Fig. 4). With no recovery of facial nerve function 18 months later, the patient underwent a lengthening temporalis myoplasty with simultaneous contralateral lower lip depressor angularis oris and labii inferioris myectomy for balance and symmetry. The patient developed moderate temporal hollowing. She subsequently underwent revision of the tendon insertion site 3 years later. At 3 months postoperatively, she demonstrated improved excursion and symmetry of her smile. (See Video, Supplemental Digital Content 1, which demonstrates the patient in case 1, a 10-year-old girl who underwent unilateral lengthening temporalis myoplasty and subsequent revision. Preoperative and postoperative perioral function is recorded, [video](http://links.lww.com/PRS/B655).)

**Case 2**

An 8-year-old boy with Möbius syndrome (patient 12 in Table 1) and complete bilateral facial paralysis underwent smile restoration with a lengthening temporalis myoplasty on the left and a left lower lid ectropion repair with a splitthickness skin graft. At 2 months, the patient was noted to have decreased right facial excursion and symmetry (Fig. 5). The right temporalis myoplasty was revised, and the patient developed a postoperative infection requiring incision and drainage. At 6 months follow-up, the patient demonstrated improved excursion and symmetry of her smile.
restoration with single-stage bilateral lengthening temporalis myoplasties (Fig. 5). The patient required a 4-day hospitalization and was discharged to home with an unremarkable postoperative course. Three weeks after surgery, the patient was started on facial therapy, including biofeedback and mirror exercises. He demonstrated excellent symmetry and mobility of the smile with 13 mm of oral commissure excursion and good nasolabial fold production. (See Video, Supplemental Digital Content 1, which demonstrates postoperative perioral function following a bilateral lengthening temporalis myoplasty procedure for the patient in case 2, http://links.lww.com/PRS/B656.)

Case 3

A 10-year-old girl (patient 13 in Table 1) presented with a 14-month history of complete left hemifacial paralysis following resection of a medulloblastoma (Fig. 6). Given the total lack of reinnervation of the facial nerve and persistent facial asymmetry, the patient was recommended for a lengthening temporalis myoplasty for lip reanimation. She also underwent contralateral depressor angularis oris and labii inferioris myectomy for lower lip balance. The patient was hospitalized for 4 days and had an unremarkable postoperative course. She demonstrated immediate mobility of the oral commissure (11-mm excursion) with improvement of facial symmetry. She developed effortless activation of the smile within 3 weeks and required no revisions. (See Video, Supplemental Digital Content 3, which demonstrates postoperative results following unilateral lengthening temporalis myoplasty for the patient in case 3, http://links.lww.com/PRS/B657.)

DISCUSSION

The lengthening temporalis myoplasty is an intriguing take on an infrequently used muscle transfer for facial paralysis. By advancing the temporalis in an antegrade fashion, the temporalis tendon achieves better elongation for upper lip and oral commissure attachment without the need for intervening grafts. The vector of excursion is optimal for smile restoration. There are numerous potential benefits to using lengthening temporalis myoplasty for smile reanimation over vascularized free muscle transfers such as the gracilis. First, by eliminating the microsurgical component, operative time is shortened substantially. There is no secondary donor site requiring healing, and postoperative vascular compromise is not a concern. Also, there is no requirement for postoperative intensive care unit stay or prolonged hospitalization. It is even conceivable that lengthening temporalis myoplasty can be performed on an outpatient basis in selected patients. Second, the actuating temporalis muscle is not denervated; therefore, the time to animation is negligible over free tissue transfer, which requires time for nerve regeneration. This has an impact on immediate results and on initiating facial therapy. Third, the problem of excessive cheek bulk common to free muscle transfers is avoided because of the trajectory of the temporalis tendon deep to the zygomatic arch and within the buccal fat pad. Fourth, smile reconstruction can be tested intraoperatively by direct muscle stimulation and adjusted as necessary.6,20,21 This is an important advantage of lengthening temporalis myoplasty over free muscle transfer. By stimulating the muscle, the degree of expected postoperative movement is predicted along with vector of excursion and accurate placement of anchoring sutures. Fifth, placement of a nasolabial incision is helpful in defining the location of the nasolabial fold, exactly at the junction of the upper lip and cheek skin.22 It also aids in the adjustment of anchoring sutures for the temporalis tendon insertion. In some instances, coronoidectomy can be performed through this incision without the need for zygomatic arch osteotomy. Lastly, by shortening the surgical time, ancillary procedures can be performed to help improve global facial symmetry. Contralateral lower lip depressor myectomy or Botox injection, ipsilateral lagophthalmos correction, ipsilateral brow elevation, and midface lift can all be performed in a single, comprehensive operative effort.

There is one large disadvantage noted. Less than ideal excursion resulted from tendon avulsion from the insertion site and/or muscle adhesions within the cheek and subzygomatic region. In our study, 64 percent of patients required revision surgery, including tenolysis and readvancement of the temporalis tendon. This occurred
despite measures to reduce tension on the temporalis muscle, including use of Botox on contralateral facial musculature and placement of an indwelling local anesthetic infuser catheter near the neurovascular pedicle. This is admittedly a rather high rate. However, revisions were all performed on an outpatient basis through the nasolabial fold incision only. In older children and adults, it is conceivable that this type of revision can be performed under local anesthesia. Nonetheless, as experience with lengthening temporalis myoplasty evolves, refinements in technique may eliminate this problem or reduce it significantly.

Another disadvantage is one that is common also to free gracilis muscle transfers that use the masseter nerve for stimulation. Given that the temporalis muscle is supplied by the trigeminal nerve, it lacks an element of spontaneity. Muscle retraining is a requirement and may not occur for months to years. However, other reports have indicated a return of spontaneous or effortless smile activation in the majority of patients. These studies reiterate the existence of cortical plasticity and reorganization of the motor system to functionally relevant muscles.

Next, although placement of a nasolabial fold incision is helpful in defining the desired location on the paralyzed side and for insetting the temporalis tendon, the presence of an external incision is not ideal. Some studies have suggested that subdermal plication more accurately defines this structure by means of a facial skin flap. The difficulty lies in reproducibility. Also, the presence of a nasolabial fold incision allows easy access for revision surgery when necessary, without the need to elevate large facial skin flaps. Although a buccal incision is an attractive option in accessing the temporalis tendon, it still proves challenging in the precise placement of tendon-anchoring
sutures in the perioral region required for recreation of the nasolabial fold.

Also, three patients demonstrated moderate temporal contour deficit several months postoperatively. There are three potential sources for this problem. As part of the learning curve, earlier cases were performed with complete mobilization of the temporalis within the temporal fossa as opposed to only the posterior half. The visual portion of the temporal fossa is the anterior portion. Despite resecuring the muscle to a cuff of strong fascia along the anterior temporal crest, thinning of the overlying tissues was observed. Alternatively, or synergistically, elevation of the coronal flap over the zygomatic arch must include a fat pad that resides on the deep temporalis fascia. This was inadvertently omitted in early efforts. The fat pad must then be excised if left on top of the temporalis, because it interferes with

Video 2. Supplemental Digital Content 2 demonstrates postoperative perioral function following a bilateral lengthening temporalis myoplasty procedure for the patient in case 2 (patient 12 in Table 1). [http://links.lww.com/PRS/B656].

Fig. 6. Case 3 (patient 13 in table 1). (Above, left) Complete left facial paralysis nearly 3 years after resection of a medulloblastoma. Preoperative markings and asymmetric smile are shown. (Above, right) Postoperative appearance at 7 months after lengthening temporalis myoplasty. (Below) Oblique view of postoperative smile activation.
The more traditional temporalis turnover flap predates microvascular functional muscle transfers. In this procedure, the entire muscle or a portion of it is turned over the zygomatic arch and stretched toward the perioral region. Many disadvantages make this a less desirable option. First, excessive bulk over the zygomatic arch can be unsightly. Second, the length of muscle from the top of the origin of the muscle to the pivot point above the arch is frequently too short to reach the corner of the mouth. This requires the use of a nonvascularized interpositional fascia or tendon graft, which frequently results in adhesions, weakening, and loss of movement. In addition, a secondary donor site is required. None of the patients in this study required an interpositional graft. Third, if the entire muscle is used, there is a significant degree of temporal hollowing requiring secondary procedures to fill.

Other single-stage options for lip reanimation are available, including free latissimus dorsi, rectus abdominis, and serratus anterior flaps. These flap options promise greater spontaneity by means of coaptation with the contralateral functioning facial nerve. Proposed initially by Harii, the segmental latissimus dorsi flap involves harvesting a long length of thoracodorsal nerve that will then need to regenerate into the implanted muscle. Although some studies report favorable results, others highlight inconsistent results and a high failure rate as described by weak or no contraction. In addition, there are a wide range of reported latent periods until reinnervation occurred, from 3 to 16 months. In the pursuit of true spontaneity of smile, the two-stage cross-face nerve graft followed by free muscle graft is perhaps a better option. The length of time to reinnervation of the transplanted muscle is critical. By allowing the nerve impulse to regenerate along the cross-face nerve graft, the distance required for secondary innervation into the functional muscle is effectively shortened.

As with gracilis muscle transfer for lip reanimation, lengthening temporalis myoplasty addresses only oral commissure and upper lip elevation as it occurs with smiling. The procedure by itself does not address other sequelae of facial paralysis, such as the lack of ipsilateral lower lip depression. However, the shortened operative time offered by lengthening temporalis myoplasty allows simultaneous correction of several facial asymmetries, including contralateral lower lip depressor myectomy, lagophthalmos correction, and contralateral frontalis myectomy. In addition,
chemodenervation of overactive contralateral facial musculature with Botox can be performed quickly and easily, without any discomfort.

CONCLUSIONS

The lengthening temporalis myoplasty is an excellent and reproducible alternative to free vascularized muscle transfer for smile reanimation in facial paralysis. Some of the advantages include reduced operative time and hospital stay, quicker time to activation, and improved cheek contour without excess bulk. The disadvantages include a steep learning curve and high revision rate secondary to problems at the temporalis tendon insertion site. We observed greater predictability of smile reanimation with increased experience with the technique. Modifications and refinements can conceivably improve results further.
